The role of contraindications in prescribing anticoagulants to patients with atrial fibrillation:

a cross-sectional analysis of primary care data in the UK

Abstract

Background
Underuse of anticoagulants in atrial fibrillation (AF) is an international problem, which has often been attributed to the presence of contraindications to treatment. No studies have assessed the influence of contraindications on anticoagulant prescribing in the UK.

Aim
To determine the influence of contraindications on anticoagulant prescribing in patients with AF in the UK.

Design and setting
Cross-sectional analysis of primary care data from 645 general practices contributing to The Health Improvement Network, a large UK database of electronic primary care records.

Method
Twelve sequential cross-sectional analyses were carried out from 2004 to 2015. Patients with a diagnosis of AF aged ≥35 years and registered for at least 1 year were included. Outcome measure was prescription of anticoagulant medication.

Results
Over the 12 study years, the proportion of eligible patients with AF with contraindications who were prescribed anticoagulants increased from 40.1% (95% confidence interval [CI] = 38.3 to 41.9) to 67.2% (95% CI = 65.6 to 68.8), and the proportion of those without contraindications prescribed anticoagulants increased from 42.1% (95% CI = 41.6 to 42.6) to 67.7% (95% CI = 67.2 to 68.1). In patients with a recent history of major bleeding or aneurysm, prescribing rates increased from 44.3% (95% CI = 42.2 to 46.5) and 34.8% (95% CI = 29.4 to 40.6) in 2004 to 71.7% (95% CI = 69.9 to 73.5) and 63.2% (95% CI = 58.3 to 67.8) in 2015, respectively, comparable with rates in patients without contraindications.

Conclusion
The presence or absence of recorded contraindications has little influence on the decision to prescribe anticoagulants for the prevention of stroke in patients with AF. The study analysis suggests that, nationally, 38 000 patients with AF with contraindications are treated with anticoagulants. This has implications for patient safety.

Keywords
anticoagulants; atrial fibrillation; contraindications; general practice; stroke, prevention; therapeutics.

INTRODUCTION

Atrial fibrillation (AF) is the most common sustained cardiac arrhythmia and it is associated with a substantial increase in risk of ischaemic stroke.[1,2] Stroke risk is reduced by the use of anticoagulants.[3–8]

Anticoagulant prophylaxis has been recommended by the British Committee for Standards in Haematology since 1998 for patients with AF at elevated risk of stroke, and by the National Institute for Health and Care Excellence (NICE) since 2006.[9–11] In the UK, rates of anticoagulation remain low;[12–14] however, European studies suggest that high rates (>80%) of anticoagulation can be achieved.[15,16]

Underuse of anticoagulants is an international problem, which has often been attributed to the presence of contraindications to treatment, particularly bleeding or risk of bleeding.[13,17–21] Conversely, however, several studies in the US and Europe have found similar rates of prescribing between patients with and without contraindications.[22–24] To date, there have been no comparable studies carried out in the UK. Furthermore, there has been some inconsistency regarding which comorbidities are identified as contraindications to anticoagulant use. The Medicines and Healthcare products Regulatory Agency (MHRA) has defined contraindications to warfarin as: hypersensitivity to warfarin; haemorrhagic stroke; significant bleeding; pregnancy; within 72 hours of major surgery with risk of severe bleeding; within 48 hours postpartum; and drugs where interactions may lead to a significantly increased risk of bleeding.[25] In many studies, other comorbidities, such as risk of falls, and possible compliance issues are often included as contraindications; these may be better regarded as cautions for anticoagulant treatment rather than as absolute contraindications.[25,26]

The objective of this study was to investigate the relationship between contraindications and anticoagulant prescribing for AF in UK patients in primary care between 2004 and 2015.

METHOD

Data source

The Health Improvement Network is a database of anonymised electronic primary care records from UK general practices using Vision software. It includes coded data on patient characteristics, prescriptions, consultations, diagnoses, and primary care investigations for 3.6 million active patients registered at 587 active practices across the UK, with more than 85 million patient years of data.[27] Practices were eligible for inclusion in the study from the latest of the practice acceptable mortality recording date,[28] the Vision installation date, and the study start date (1 year prior to the first index date).

Study design

Twelve sequential cross-sectional analyses were performed on 1 May each year from

How this fits in

Underuse of anticoagulants in atrial fibrillation (AF) is well recognised internationally and is often attributed to the presence of contraindications. However, to date, no analysis has investigated the extent to which contraindications influence anticoagulant prescribing in the UK. This study indicates that contraindications, as defined in UK guidance, have little influence on the clinician's decision to prescribe anticoagulants to patients with AF with moderate to high stroke risk. This has important implications for patient safety.

2004 to 2015 (index dates). All analyses were undertaken using Stata (version 13).

Analysis

Patients with a diagnosis of AF aged ≥35 years on the index date and registered at least 1 year prior to the index date were included in the analysis. The exposure of interest was the presence of contraindications to anticoagulants. Outcome was treatment with anticoagulants.

On each index date, the proportion of patients with AF with contraindications and the proportions of eligible patients prescribed anticoagulants with and without contraindications were calculated, with 95% confidence intervals (CI). *P*-values for trends over time were calculated using χ^2 tests; *P*-values for differences between proportions of binary variables were calculated using two-sample tests for proportions. In primary analysis, patients with a $CHADS_2$ score ≥1 (moderate or high stroke risk) were categorised as eligible for anticoagulant treatment. $CHADS_2$ score was used to define eligibility as it has been in use for longer than CHA_2DS_2-VASc;[29,30] in sensitivity analysis, patients with a CHA_2DS_2-VASc score ≥1 were categorised as eligible for anticoagulants.

Definitions of variables

A diagnosis of AF was defined by the presence of a clinical code for atrial fibrillation or atrial flutter at any time prior

[a]Where recorded; ethnicity was missing in 59.2% of the patient records (decreasing from 74.4% in 2004 to 54.2% in 2015). [b]1 = Least deprived, 5 = Most deprived.

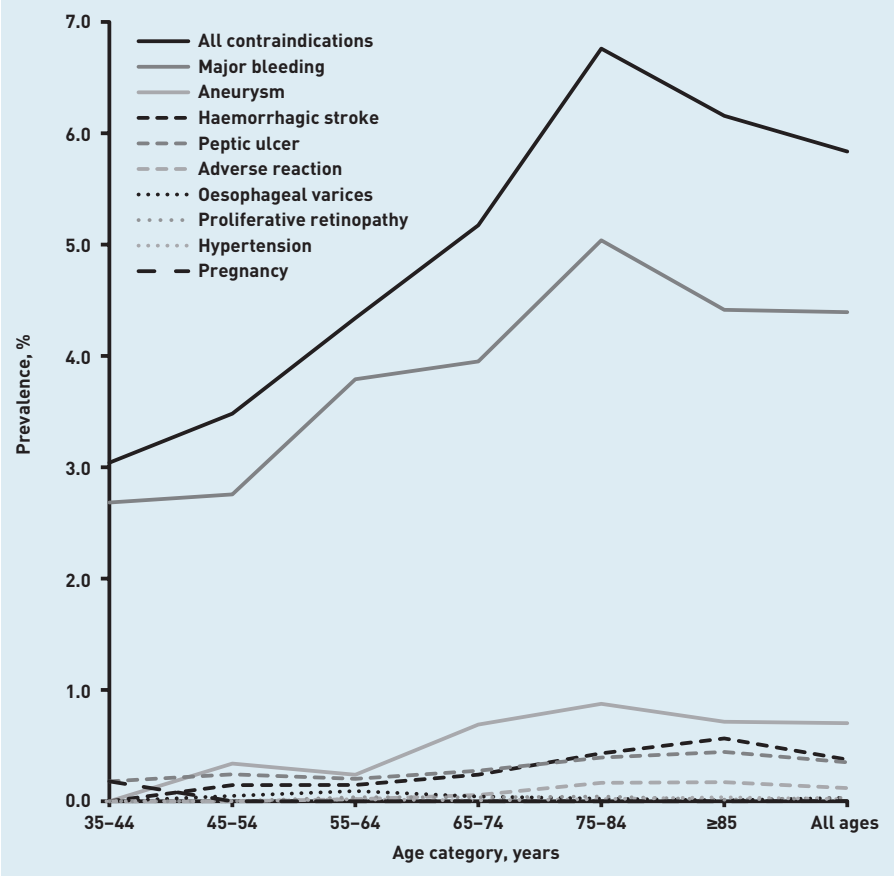

Figure 1. Prevalence of contraindications to anticoagulants in patients with atrial fibrillation by age category, 2015.

to the index date, excluding patients with a more recent clinical code indicating that AF had resolved. Current anticoagulant treatment was defined by a record of a relevant prescription within 90 days prior to the index date or a clinical code indicating the patient was receiving anticoagulant therapy within 365 days prior to the index date.

Contraindications to anticoagulants were defined in accordance with MHRA and NICE evidence.[25,26] Contraindications specific to anticoagulants other than warfarin, such as novel oral anticoagulants (NOACs) (for example, liver disease), were not included, as these do not preclude treatment with warfarin. Short-term contraindications (within 72 hours of surgery or 48 hours postpartum) and cautions for anticoagulant use were not included. Contraindications were defined as: a clinically coded diagnosis within the 2 years prior to the index date of haemorrhagic stroke, major bleeding (gastrointestinal, intracranial, intraocular, retroperitoneal), bleeding disorders (haemophilia, other haemorrhagic disorders, thrombocytopenia), peptic ulcer, oesophageal varices, aneurysm, or proliferative retinopathy; a record of allergy or adverse reaction to anticoagulants ever prior to the index date; a record of pregnancy in the 9 months prior to the index date; or severe hypertension with a mean (of the three most recent measures in the last 3 years prior to the index date) systolic blood pressure >200 mmHg or diastolic blood pressure >120 mmHg.

$CHADS_2$ scores were calculated by adding one point each for a history of congestive heart failure, hypertension, age ≥75 years, and diabetes, and two points for a history of stroke or transient ischaemic attack (TIA). CHA_2DS_2-VASc scores were calculated by adding one point each for a history of congestive heart failure, hypertension, diabetes, vascular disease, age 65–74 years, and female sex (if another risk factor was present, otherwise 0), and two points each for age ≥75 years and history of stroke, TIA, or thromboembolism. History of congestive heart failure, stroke, TIA, thromboembolism, vascular disease, and diabetes were defined by a clinical code recorded ever prior to the index date, excluding patients with diabetes with a later record indicating diabetes resolved. Hypertension was defined as either a current (previous 90 days) prescription of antihypertensive drugs or the mean of the three most recent systolic blood pressures in the last 3 years ≥160 mmHg.

RESULTS

A total of 166 136 patients with AF from 645 practices were included in the study. As an individual could contribute to the analysis in more than 1 year, a total of 735 938 records of patients with AF were included in the analysis across the 12 index dates, with a median of 63 539 (interquartile range [IQR] = 56 696–67 571) patients per year. The mean age of patients with AF across all years was 76.2 (standard deviation [SD] 11.0) years; 54.7% (n = 402 354 out of 735 938) were male. Baseline characteristics are shown in Table 1: patients with AF with contraindications were on average 1.4 (95% CI = 1.3 to 1.5) years older and 2.3% (95% CI = 2.4 to 3.4) more were male.

Around 6% of patients had contraindications to anticoagulation and this changed little over the 12-year period (range = 5.8 to 6.6%). The most common contraindication was major bleeding: 4.4% (95% CI = 4.2 to 4.6) of patients with AF in 2015. The prevalence of individual contraindications remained reasonably constant from 2004 to 2015, except for declining frequency of peptic ulcer from 0.64% to 0.35% (P<0.001) and of severe hypertension from 0.22% to 0.02%

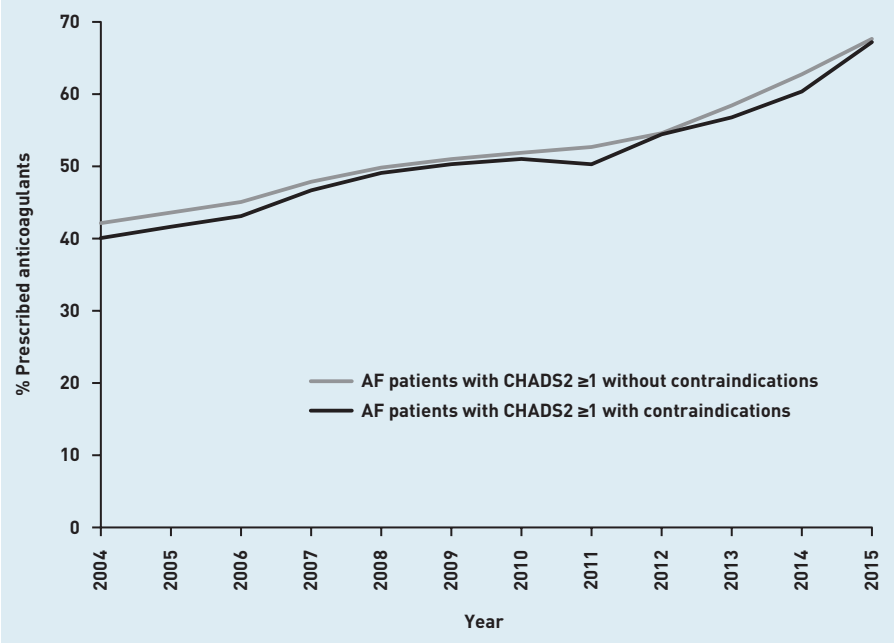

Figure 2. Proportion of patients with atrial fibrillation with and without contraindications who were prescribed anticoagulants, 2004–2015.

(P<0.001) (Appendix 1). The prevalence of all contraindications tended to increase with age (Figure 1).

The proportion of eligible patients (with a $CHADS_2$ score ≥1) prescribed anticoagulants increased from 2004 to 2015. However, in every year similar proportions with contraindications and without contraindications were prescribed anticoagulants (Figure 2). In 2004, 40.1% (95% CI = 38.3 to 41.9) of those with and 42.1% (95% CI = 41.6 to 42.6) of those without contraindications were prescribed anticoagulants; in 2015, this increased to 67.2% (95% CI = 65.6 to 68.8) and 67.7% (95% CI = 67.2 to 68.1), respectively (Appendix 2). The difference between the proportion of patients with and without contraindications who were prescribed anticoagulants in 2015 was not statistically significant: P = 0.595. In 2015, the interquartile range (IQR) for the proportion of eligible patients with AF prescribed anticoagulants by general practice was 52.6–80.0% in patients with contraindications and 61.8–72.4% in patients without contraindications.

Defining eligibility for anticoagulants using the CHA_2DS_2-VASc score (≥1) made no difference to the observed trends or to differences in treatment between those with and without contraindications (Appendix 3).

The proportions of patients with AF who were prescribed anticoagulants, and trends in prescribing, were similar between patients with the most common contraindications — major bleeding and aneurysm — and patients without contraindications (Appendix 4). In eligible patients with AF with a recent history of major bleeding or aneurysm, prescribing rates increased from 44.3% (95% CI = 42.2 to 46.5) and 34.8% (95% CI = 29.4 to 40.6) in 2004 to 71.7% (95% CI = 69.9 to 73.5) and 63.2% (95% CI = 58.3 to 67.8) in 2015, respectively. These were comparable to prescribing rates in eligible patients with AF without contraindications: 42.1% (95% CI = 41.6 to 42.6) and 67.7% (95% CI = 67.2 to 68.1) in 2004 and 2015 respectively. The proportion of patients with AF with less common contraindications who were prescribed anticoagulants was lower across the whole period but also increased over time. In 2015, anticoagulants were prescribed to 44.1% (95% CI = 32.8 to 56.1) with an adverse reaction, 54.3% (95% CI = 47.5 to 61.0) with gastrointestinal disorders, 38.1% (95% CI = 31.9 to 44.8) with haemorrhagic stroke, 54.5% (95% CI = 25.6 to 80.7) with severe hypertension, and 83.3% (95% CI = 58.2 to 94.7) with proliferative retinopathy.

Treatment of patients with AF with NOACs began in 2010 and their use has increased steadily since then (Appendix 5). In 2015, slightly more patients with contraindications were prescribed NOACs than vitamin K antagonists: 19.0% versus 17.4% (P = 0.061).

DISCUSSION

Summary

This analysis demonstrates that patients with AF with contraindications are just as likely to be prescribed anticoagulants as those without contraindications. The proportion of patients with AF with contraindications who are prescribed anticoagulants is increasing over time, mirroring the rise in prescribing to those without contraindications. This suggests that, in practice, the presence or absence of most contraindications has little or no influence on the clinician's decision to prescribe anticoagulants to patients with AF.

Strengths and limitations

The analysis was performed in a large general practice dataset that is generalisable to the UK population; the clinical data are routine and therefore comprise the information that GPs use for clinical decision making. AF diagnosis was often corroborated in the patient records, although it was not possible to confirm all diagnoses of AF; however, in a sample of 131 patients with AF diagnosed in UK primary care in 2006, 84% were found to have either a primary or secondary care electrocardiogram confirmation of their diagnosis.[31] Care was taken to exclude patients with 'AF resolved'.

Some anticoagulated patients may be omitted if they are managed entirely in hospital, and treatment rates may therefore be underestimated. However, this is attenuated by the inclusion of clinical codes for anticoagulant/international normalised ratio monitoring, in addition to prescription information, in the definition of anticoagulant use; furthermore, most anticoagulants are prescribed in primary care, and any underestimation is therefore likely to be small.

Most variables were defined by the presence of relevant clinical codes in the primary care record. Diagnoses that are part of the UK Quality and Outcomes Framework assessment are likely to be well recorded for most/all of the study period; clinically significant conditions, such as major bleed, which have important implications for prescribing of drugs other than anticoagulants, are also likely to be well recorded. However, recording of other medical conditions may be incomplete. There is no independent corroboration of the presence of contraindications, but the information used in the study is the same as that used by GPs for decision making, and contraindication rates are comparable with those found in other studies.[16,23] Some contraindications may be inaccurate, for example, haemorrhagic stroke may be reclassified as ischaemic stroke; however, diagnosis of haemorrhagic stroke is generally accurate in primary care records.[32] Some contraindications may be the result of previous anticoagulant treatment.

In addition to consideration of the presence/absence of contraindications, the decision to treat may also be influenced by cautions for anticoagulant use, such as the risk of falls or issues with treatment compliance. However, this should reduce rather than increase the likelihood of prescribing anticoagulants. Additionally, no information on patient preferences was available, although patients are often guided by GPs with regard to preventive medicine.[33]

Comparison with existing literature

Contraindications have often been cited as a reason for not prescribing anticoagulants.[17,19–21] However, this analysis suggests that contraindications do not stop clinicians from prescribing; this agrees with findings from studies in the US and Europe.[22–24] It is unclear why many patients with AF without contraindications are not prescribed anticoagulants, while patients with contraindications are.

Implications for research and practice

The study's findings have important implications for patient care. Alongside underuse of anticoagulants in patients with AF, there may be significant overtreatment of patients with contraindications. Based on the recorded prevalence of AF in recent data there are 1.03 million UK patients diagnosed with AF.[34,35] Of these, 59 000 (5.8%) have contraindications to anticoagulants, 57 000 (96%) of those with contraindications have a $CHADS_2$ score ≥1, and 38 000 (67.2%) are treated. This represents a significant concern for patient safety.

Although the balance of risks and benefits of using anticoagulants is favourable in patients with AF who do not have contraindications, it is unclear whether this also applies to patients with contraindications. Further work is needed to determine whether outcomes are worse among contraindicated patients with AF who are treated with anticoagulants than among those who are not, or whether the reduced stroke risk offsets any other potential adverse events. There is some recent evidence suggesting that resuming anticoagulant therapy may be beneficial in patients with AF who survive warfarin-related intracranial haemorrhage.[36,37]

Further work is needed to determine which patients with contraindications may still benefit from anticoagulant treatment. Qualitative research is needed in order to reveal the reasons why clinicians prescribe to patients with contraindications and why they do not prescribe to many patients without.
